### Abstract

The French coast of the Atlantic and English Channel (EC) is promising for the development of Marine Renewable Energy (MRE), including wind, wave, and tidal stream, due to the high velocity of currents in some parts of the area. This paper, focusing on wind and tidal energy, discusses how the implementation of MRE converters influences biodiversity, and vice versa, through biofouling and reef effects. The understanding of these interactions requires the knowledge of the hydro-sedimentary conditions and the macrofauna. The research on these topics, performed at the Continental and Coastal Morphodynamic laboratory (M2C) (UNICAEN, France), is presented through a multi-disciplinary approach by i) studying the hydrodynamic conditions and the macrofauna in Alderney Race, ii) studying the biofouling effects on tidal turbines and their influence on the turbulent wake, iii) assessing the hydro-sedimentary impacts induced by the offshore wind farm, like scouring, and iv) taking an ecosystem approach on MRE, such as the reef effect. From an ecological perspective, the reef effect can be responsible for changes in the structure and function of the ecosystem. Although several studies have analyzed this effect at the species-or community-scale, the propagation

of the reef effect at the ecosystem-scale remains unclear. Thus, understanding these ecosystem-scale effects is urgent for future research. From an engineering perspective, biofouling changes the structural characteristics (i.e., supplementary mass) of the converters and thus, affects their performance.

**1. Introduction**

The European Union (EU) had set a target to derive 20% of its consumed energy from renewable energy sources by 2020. With more than 11 million km<sup>2</sup> of water under its jurisdiction, France holds a huge potential for marine renewable energy. Currently, the construction of eight anchored offshore wind farms (OWFs) and four floating OWFs has been planned in metropolitan France (Figure 1). Among them, five anchored offshore wind farms will be built on the English Channel.

**Figure 1** Marine renewable energy development along the French metropolitan coast.

Till the end of 2020, no OWFs have been constructed due to the long administrative procedures and numerous appeals in courts at the French and the European levels [1]. Nevertheless, several

studies have been performed to identify the environmental conditions and ecosystem functioning in selected sites before the implementation of OWFs. These surveys considered several biological groups, including macrobenthos, fish, birds, and mammals (including bats), while assessing the quality of seawater and hydro-sedimentary conditions.

Tidal energy is complementary to wind energy. The tidal power in Europe is estimated at 10 gigawatts (GW), with 4 GW in France. French tidal energy sites are located in Brittany (Fromveur and Bréhat) and Normandy (Raz Blanchard) (Figure 1). The site with the highest tidal energy is the Alderney Race (Raz Blanchard) (3 GW). However, it is also the most complicated site due to complex hydrodynamics, with strong tidal currents (up to 12 knots), ocean waves, highly-energetic turbulent cells, and an uneven sea bed with different geological features (e.g., submarine faults, pebble dunes, etc.). Ten turbine-farms should be installed in Alderney Race to obtain a total power of 20 MW. The first French tidal turbines were connected to the electrical network in 2019 in the Ushant Race at Fromveur and at Bréhat (Figure 1).

In the last decade, research laboratories at the University of Caen Normandy had invested in renewable energy development in the marine environment, especially in the Normandy territory at the western part of the English Channel, in the north of Cotentin in the Raz Blanchard area, and the eastern part of the EC in the extended Bay of Seine.

The Continental and Coastal Morphodynamic laboratory (M2C) had developed multi-disciplinary approaches, such as in situ observations, high-frequency radar measurements, physical experimentations, trophic food models, and numerical modeling (Figure 2). The challenge was not only to accompany the development of MRE for each scientific discipline but also to share expertise and develop common projects on ecosystem functioning. This could be achieved by using physical and numerical modeling at different scales of observations, ranging from the consequences of biofouling of tidal turbines on energy production to the regional suspected impacts of offshore wind farming. Although previous studies have highlighted that the colonization of MRE structures by marine species (also called biofouling) can be responsible for both ecological and engineering consequences, its effects at the ecosystem-scale and on the performance of the offshore infrastructure remain poorly understood. Using a multi-disciplinary approach comprising benthos ecology, trophic web, and numerical modeling, along with expertise on the characteristics of the EC, the M2C laboratory can make an important contribution to the understanding of key issues surrounding the MRE in the EC. The EC is a coastal sea with a strong tidal regime and dominant western winds, which ensures large-scale electricity production in the future. Notably, the M2C is also a member of the Working Group on Marine Benthos and Renewable Energy Developments (WGMBRED), a part of the International Council for the Exploration of the Sea (ICES), since 2013. Thus, this paper aims to present the progress of our research in the development of MRE in the EC.

## 2. Context: The English Channel, a Megatidal Sea

The English Channel (EC) is a shallow epi-continental sea shared between the United Kingdom in the north and France in the south, with a maximum depth of 174 m in the Hurd Deep (150 km in length and 1.5 to 5 km in width) (Figure 1) [2]. Its western basin is deeper than the Eastern basin and is influenced by the Atlantic waters. It shows the presence of a summer thermocline offshore Plymouth, while the eastern basin is mainly affected by the input of freshwater from the Seine River. The tidal regime is dominated by semidiurnal tides with a period of 12 h and 25 min. The tidal ranges are greater along the French coast, mainly in the Mont-Saint-Michel Bay than along the British coast. The tidal residual propagates from the west to the east, with a water replacement time of approximately 500 days. Due to the Coriolis force, current velocities are higher along the French coast than the English coast, reaching greater than three knots in north Brittany, off the Cotentin Peninsula. In the Dover Strait, velocities exceed eight knots off the Cap de La Hague. Significant gyres are present around the Channel Islands and to the east of the capes of Fréhel, Barfleur, Antifer, and Gris Nez. Tidal currents dominate sedimentation processes; extensive pebbly sediments dominate areas of strong tidal currents located offshore and to the east of the capes, whereas fine sands and muddy fine sands appear in areas of weak tidal currents in bays and estuaries. Coarse sands and pebbles cover more than 80% of the EC seabed area; another particular feature of the sediments is their high proportions of calcareous biogenic material, reaching up to 80% in the bioclastic sediments in the central part of the western EC [2]. Located between 48° 30' N and 51°

10' N, EC is a temperate sea and is a biogeographical transition zone between the Lusitanian and Boreal provinces, influenced by a balance between warm, temperate species during warm periods and boreal species during cool periods [2].

Moreover, the EC is among the most active coastal marine zones where cumulative human impacts are the greatest. The eastern basin is more impacted than the western basin due to widespread traditional activities such as maintenance of fisheries and the emergence of new activities such as granulate extraction and offshore wind farm installations [2, 3].

### 3. Hydrodynamic conditions in Alderney Race

To determine the shear of surface currents and sea states, high-frequency (HF) radars were implemented in Cap de la Hague in 2017. They monitored in real-time the surface hydrodynamic (currents and sea states). This innovative system, using two transmitting frequencies (24.5 MHz and 13.5 MHz), produced rare data of the spatialized hydrodynamic of the Alderney Race. First, these data have enabled validation of the numerical model (3D-fully wave-current model); for surface currents, a good agreement has a Root-Mean-Square-Error between 14 and 40 cm/s for the neap tide and between 18 and 60 cm/s for the spring tide [4, 5]. Maximum errors were found in shallow zones with consistently high current velocities. Second, some regions with a strong current shear were highlighted in the radar data; a new methodology for the radar data analysis in such regions is under development.

In addition to the HF radar measurements, some efforts in numerical modeling were performed during HY2DM. An innovative Large Eddy Simulation (LES) method, called LANS-alpha, was implemented in a coastal hydrodynamic numerical model, MARS3D [6], to improve the simulation of the marine turbulence [7, 8]. This method differs from the classical dissipative LES in that this is a reformulation of the equations of fluid mechanics with alteration of the existing non-linear terms and the addition of extra non-linear terms. LANS-alpha does not use a sub-grid scale viscosity, unlike dissipative LES. After a validation step for a wind-driven motion over a seamount, this method was applied to the Alderney Race. A re-energization of the flow was observed with two types of turbulence energy decay in the inertial zone as expected for two-dimensional turbulence. This method mainly affects the turbulence induced by deformation; rotation-induced turbulence is slightly modified. The computing time is reduced by 30% by the use of LANS-alpha.

Furthermore, M2C researchers studied the impact of the wave-current interactions on the tidal stream energy using numerical modeling. The 3D-fully wave-current simulations were performed with the coupled model, which combined the hydrodynamic numerical model, MARS 3D, and the spectral wave model, WAVEWATCH-III [9]. Data from this coupled model were tested and compared with in situ observed data and were found to have good scores [10]: i) the RMSE related to the sea level was around 0.13 m and 0.44 m at Cherbourg and Dièlette, respectively, ii) the PBIAS (percent bias) related to wind at ten-meters height was around 10% and lesser than 4% for magnitude and direction, respectively, iii) the significant wave height PBIAS was around 6% with an  $R^2$  (coefficient of determination) of 0.97, iv) the NRMSE (Normalized RMSE) related to the magnitude of current was around 0.11. The inclusion of wave effects has contributed to a decrease in the error in tidal energy estimate, which was lesser than 10% for the considered time-period (21-25 November 2017). Additionally, the impact of Eleanor's storm (on 2-3 January 2020) on tidal energy was simulated using the coupled model. This storm occurred during a spring tide. A strong reduction in tidal current

magnitude (0.4-0.5 m/s) was observed with PBIAS reduction by a factor of 1.89 and 1.76 for simulations with only tides and with both tides and wind, respectively [11].

#### 4. Macrofauna in the Alderney Race

In the research project entitled “Pile & Tide”, financed by the ADEME (Agence de l’Environnement et de la Maîtrise de l’Energie), the M2C laboratory was in charge of the investigation of the benthic habitats (seabed composition and benthic communities) in the Alderney Race strait. The area is located in the western basin of the English Channel to the North of the Normand-Breton Gulf, with the strongest tidal currents in Europe. The water depth here varies between 20 and 80 m. The sea bed is mainly composed of granite and calcareous rocks of the Cambrian, Silurian, and Cretaceous ages; some surficial sediments in small patches between rocky substrate are mainly composed of gravel and pebbles [12].

The data on the macrofauna of such a dynamic area are very rare and were obtained in the 1970s from the doctoral thesis of Retière (1979) [13], who described a mussel community, *Musculus discors* (L., 1767), in the area of the Alderney Race. Additionally, the horse mussel, *Modiolus modiolus* (Lamarck, 1799), was reported to form mussel beds. However, *M. modiolus* was not recorded recently in samplings in 2015-2016 [12], and its persistence in this area, which corresponds to the southern limit of its distribution in the north-eastern Atlantic, needs to be confirmed

During three sampling campaigns between 2015 and 2016, a total of 38 benthic stations were visited with a Rallier du Baty dredge. A single gear was used to sample the sea bed in hydrodynamic areas. Of the 38 operated dredges, 24 were unsuccessful, containing little to no sediments, and only 14 yielded sufficient volume of sediment (0.5 to 32 L) composed of gravels and pebbles with or without sessile epifauna [12]. Despite a low number of effective stations, the collected fauna showed high diversity with 140 different taxa, dominated by crustaceans (69 taxa). The fauna was characterized by small species living either in interstitial positions, or as infauna, or protected (like erect hydrozoans). Most of the sampled species were adapted to live in high-energy hydrodynamic conditions and hard irregular sea beds. Following Michez et al. (2015) [14], three benthic habitats were identified [12]: (1) very mobile and coarse infralittoral sediments with scattered fauna; (2) circalittoral pebbles under strong hydrodynamic conditions with scattered fauna; and (3) mobile coastal circalittoral gravel and pebbles consisting of *Spirobranchus triqueter* (L., 1758), barnacles, and encrusted bryozoans. New locations of two crustacean species in the English Channel were reported for the amphipod, *Elasmopus thalyae* (Gouillieux and Sorbe, 2015) [15], found at the soft and hard bottoms of the Arcachon Bay [16] and the tanaid, *Zeuxo holdichi* (Bamber, 1990), described from the Arcachon Bay [17].

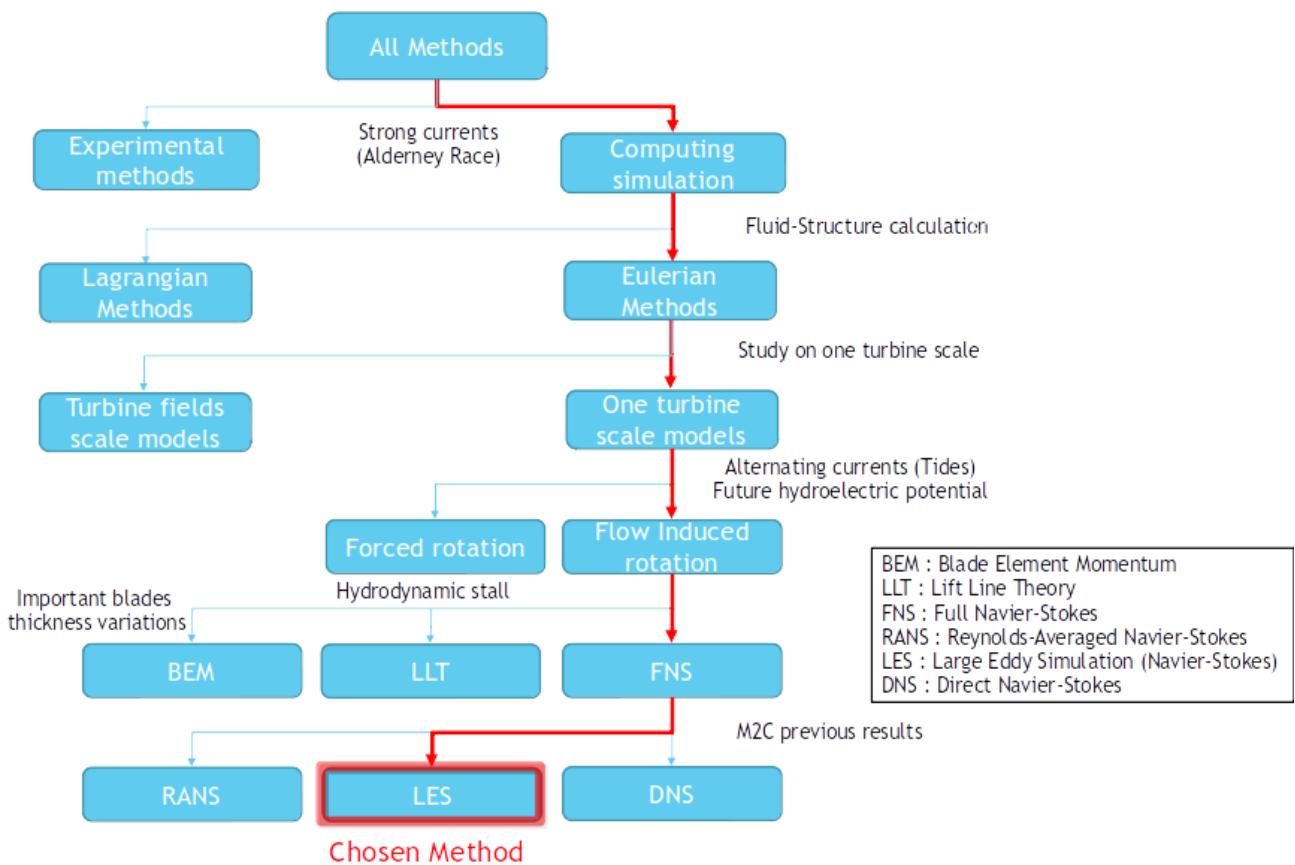

To provide additional information to standard benthic observations, Foveau et al. (2017) [18] had developed a new underwater imagery system to monitor the seafloor and benthic communities of the Alderney Race. Despite the difficulty in the acquisition, the underwater images highlighted the heterogeneous nature of the seabed in the Alderney Race. A total of 380 photos of the seafloor were obtained during a 2016 survey, among which 38% were usable [18]. Two main sediment types were recognized: (1) gravel and blocks, mixed in a more or less cohesive way, and (2) bedrock. Sessile fauna was identified from the images, which included the barnacle, *Balanus crenatus* (Bruguère, 1789), hydrozoans belonging to the genus *Sertularia*, as well as poriferans and

bryozoans. From the images, it was not possible to determine mobile species due to their small size and infaunal lifestyle.

In summary, the sea bed was mainly composed of a hard bottom with small enclaves of coarse sediments in the spaces between large granite blocks. This area remained difficult to explore due to its high heterogeneity and steep slopes (in some places, the vertical depth varied by 10 m over a horizontal distance of 5 m [18]). Due to strong currents, the hard bottom was poorly colonized by sessile fauna, except the mussel, *Musculus discors*, and the barnacle, *Balanus crenatus*, which dominated the epifauna. Nevertheless, the infauna was rich and consisted mainly of small species adapted to live in clean mobile sediments.

## 5. Impact of Macrofauna on Tidal Turbine Performances

After identifying the macrofauna of the Alderney Race, the M2C researchers investigated its influence on the tidal turbine performance. In particular, the effects induced by biofouling on the turbulent wake were studied. Assessing these effects is a relevant issue for the tidal industry to minimize the maintenance of the turbines. Numerical modeling is challenging due to the need to solve the geometry of biofouling species in the mesh and to produce long time series for the diagnosis of turbine performance. Computational Fluid Dynamic (CFD) simulations were carried out to understand how species changed the flow near the blades using three main types of turbulence models (RANS, LES, DNS) available in OpenFoam [19]. The computational domain was composed of two meshes-one was fixed, while the other rotates and contained the rotor. The Arbitrary Mesh Interface (AMI) method was used to send the flow from one mesh to the other. As explained in Figure 3, the LES (Large Eddy Simulation) method with the Smagorinsky model was the best choice for this application; turbulent structures induced by biofouling were better represented than using RANS, and the computing time was less than using the DNS model. The simulated turbulent wake was found to be sensitive to the presence of organisms. When the colonization was located near the leading edge, the effects were much more significant. Moreover, a single organism or a small colony can disrupt the wake more than a large colony, leading to a sharkskin effect. Three-dimensional effects were also investigated by Robin et al. (2019) [20] for the cases of forced and flow-induced rotations. Flow-induced rotation conforms to the energy chain better than forced rotation. In flow-induced rotation, the primary energy contained in the flow is transformed into mechanical energy before being converted into electricity. The wakes in both cases were compared, and, as expected, the signals were similar for similar speeds of rotation. It showed that flow-induced code does not interfere with the flow results. Moreover, biofouling modifies the rotor weight, which mainly affects the turbine's behavior when the flow strongly depends on time. The modification of the mass impacts the rotor's restart (transition mode) if it is heavily loaded with organisms. This problem was unlikely to occur in the Alderney Race but can appear at tidal turbines in shallower seas. The M2C researchers are currently working on the coupling between OpenFoam (CFD) and Dorothy (vortex model) numerical codes to reduce the computing time. OpenFoam will handle the close-blade field while Dorothy will solve the wake in the far-field. Thus, we will have an efficient tool to study the impacts of different colonizations on the performance of the tidal turbines.

**Figure 3** Decision tree for CTD method selection.

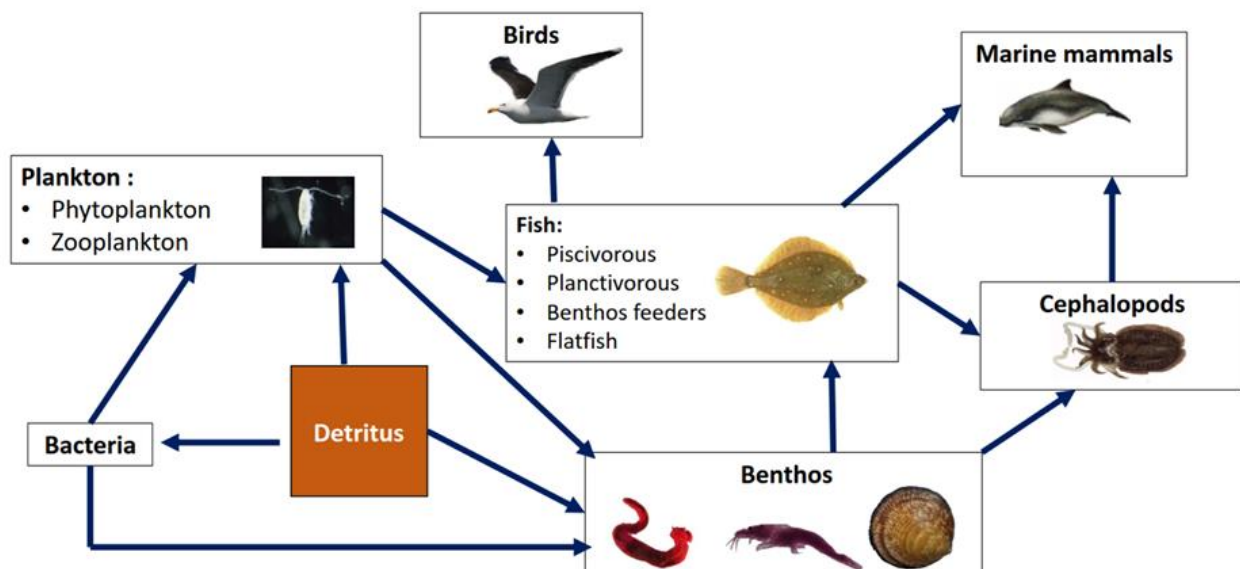

## 6. Assessment of the Environmental Impacts of the Offshore Wind Farm Foundations

In the Ofelia project (Interreg IVa France-England), the M2C was in charge of the numerical modeling for the assessment of the hydro-sedimentary impacts of the monopiles on the future Courseulles s/mer wind farm [21, 22]. A subgrid-scale parameterization was developed and implemented in the three-dimensional hydrodynamical model, MARS 3D. This parameterization, based on Ganthy (2011) [23] and Kombiadou et al. (2014) [24] for the *Zostera noltei* meadows, was able to reproduce the changes in the flow due to the monopiles and the impacts on the seabed morphology by adding drag forces to the momentum and turbulence equations. Comparisons with simulations where the monopiles were explicitly solved in the mesh were done to evaluate the performance of the parameterization over a tidal cycle. We observed similar behaviors between the two types of simulations, where currents increased at the side of the monopile and decreased in front and downstream of the monopile. For a network of four monopiles, and according to the tidal cycle, wakes downstream of the monopile interacted with the other monopiles modifying the current velocity. For the effect of sediment transport, the increase in the flow around the monopile caused resuspension and erosion (scour), while the decrease in the flow generated sediment deposits around the monopile. These effects were in agreement with the ones observed experimentally (in-situ or laboratory) [25, 26]. This new parameterization may be used to efficiently simulate the hydro-sedimentary changes induced by the monopiles. For other types of foundations, like gravity-based or tripod, results have to be carefully interpreted, and the expressions of the forces need to be adjusted.

## 7. Toward an Ecosystem Approach of Marine Renewable Energy

Noting that there was no integrated study of the effects of MRE on the ecosystem in the countries where they were implemented [1, 27], the M2C laboratory promoted a sampling strategy to collect local data for future environmental monitoring programs of OWFs. The M2C developed an MRE ecosystem approach based on local biomass data (i.e., zooplankton, meiofauna, benthos, and demersal fish) and the link between demersal fish and the benthos, through stomach content studies [1, 27]. Then, a trophic web model based on these data was built. In parallel, the M2C, in collaboration with the Biology of Aquatic Organisms and Ecosystems (BOREA) laboratory, explored a new way to understand the potential impacts of OWFs through food web models and flow analysis. They developed an ecosystem-integrated view of the future CSM OWF site to describe the marine ecosystems before OWF construction and to simulate the reef effect after OWF construction (Figure 4) [27, 28]. Among the different trophic web modeling approaches currently available, the modeling tool Ecopath with Ecosim (EwE) was used [29-31] to describe the initial state of both future OWF sites. This was a mass-balance, zero-dimension modeling approach, which had previously been used to analyze the impact of a wide range of anthropogenic perturbations on marine ecosystems such as fishing, sea dumping operations, new species introductions, and infrastructure development [32-37]. However, surprisingly few studies have combined trophic web modeling strength with OWF impact assessment [27, 38]. Thus, the M2C laboratory applied the EwE approach to model the trophic web of the area intended for the CSM OWF and the DLT OWF construction to obtain knowledge of both the systems and to characterize their ecological properties through Ecological Network Analysis (ENA) [1, 27, 28].

**Figure 4** Trophic web of the Courseulles-sur-Mer ecosystem model (modified from Raoux et al., 2017 [27]).

### 7.1 Ecopath Models of the Future CSM OWF and DLT OWF Sites

An ecosystem model composed of 37 compartments (from phytoplankton to seabirds) was built to describe the situation “before” the CSM OWF construction and was called Before Offshore Wind

Farm (BOWF) [27]. The compartment selection and aggregation were based on trophic interactions. Additionally, special attention was given to commercial species by placing them in monospecific compartments (for more details, see Raoux et al., 2017 [27]). This model was built by using the data collected during the Environmental Impact Assessment (EIA) of the CSM OWF site. The main results highlighted that the CSM trophic web is controlled by an intermediate trophic level dominated by the keystone species, the pouting (*Trisopterus luscus*). Similarly, an ecosystem model (from phytoplankton to seabirds) was built to describe the structure and function of the DLT OWF construction site. Ecosystem species were grouped into 28 compartments of similar trophic behavior (same prey and same predators). Additionally, benthic invertebrate macrofauna was subdivided into consumed and non-consumed species (more details in Pezy et al., 2018a). This model was built by using the data collected from sampling operations following the methods described by Pezy et al. (2018a) [1]. The main results highlighted that the trophic web is most likely detritus-based and that the ecosystem biomass is dominated by “non-consumed benthic invertebrates”. This could be a trophic dead-end for fish due to the size of these filter feeders compared to the size of the fish in the DLT area. All information regarding the input and output parameters of the CSM and the DLT Ecopath models can be found in Raoux et al. (2017) [27] and Pezy et al. (2018a) [1], respectively.

The area intended for the construction of the CSM OWF and the DLT OWF had gravelly sand. The ecosystem biomass of both sites was dominated by benthic invertebrate filter feeders, with biomass of 22.5 gC.m<sup>-2</sup> at the CSM site (dominated by the bivalve, *Polititapes rhomboides*) and 45 gC.m<sup>-2</sup> at the DLT site (dominated by the dog cockle, *Glycymeris glycymeris*, and the banded carpet clam, *Polititapes rhomboides*) [1, 39]. The comparison of the ENA between the gravelly sand of the OWF planned at CSM and at DLT highlighted that the total activity and ascendancy values were higher for the CSM OWF. This was because the CSM OWF model had a greater number of compartments than the DLT OWF model and a higher intake of nutrients from the Seine River [40]. Additionally, between the two sites, the recycling value was higher at the area intended for the DLT OWF construction due to higher bivalve biomass at the DLT site [39]. This result highlighted the importance of considering an ecosystem perspective with physical and biological coupling in the OWF surveys. Thus, even if both these sites had a similar type of sediment, they had different emergent properties that could be explained partly by higher biomass and species richness at the DLT site.

## **7.2 Simulation of the Reef Effect Due to the OWF Construction**

The reef effect has been described for epibenthic and demersal fauna as well as for benthopelagic fish (including commercial species) close to wind farm foundations [27, 28, 41-47]. Filter feeders, such as mussels and amphipods, tend to colonize and dominate the vertical structures of the turbines. Benthic predators such as crabs commonly inhabit the base of the foundations, and the scour protections [48]. In the North sea, several fish species (such as the pouting (*Trisopterus luscus*) and cod (*Gadus morhua*) have been shown to aggregate around the foundations, possibly because of the enhanced food supplies which could potentially improve their productivity [42-44]. Additionally, studies have also pointed out that the increase in the biomass of filter feeders, such as the blue mussel (*Mytilus edulis*), on turbines can alter the pelagic primary productivity by reducing the local concentration of phytoplankton [46, 47, 49]. This depletion of phytoplankton and primary

production affect the benthic and fouling community and is responsible for changes in the functioning of the ecosystem, such as the local biogeochemical cycle [46, 49].

As mentioned previously, so far, there is no holistic study on the impact of the reef effect induced by OWF constructions on entire ecosystems. Hence, as a complementary approach to the traditional impact assessment, the objective of the M2C laboratory, in collaboration with BOREA, was to develop an integrated ecosystem overview of the reef effect. Thus, an Ecosim model (the temporal dynamic module of EwE) was derived from projecting the evolution of the ecosystem over the next 30 years, after the simulated increase in the biomass of specific benthic and fish compartments associated with the OWF construction. Key findings from these analyses showed that the reef effect is predicted to lead to a detritivore-dominated trophic web [27], which is similar to the hypothesis of Norling and Kautsky (2008) [50]. An increase in the biomass of benthic invertebrates and benthos-feeding fish in response to the reef effect is predicted to attract apex predators, as hypothesized by Lindeboom et al. (2011) [45] and by Reubens et al. [44]), who demonstrated that poutings fed on the macrobenthos produced on the Thornton bank wind turbines in the Belgian part of the North Sea. Additionally, as mentioned previously, colonization of MRE structures by epibenthic communities (mussels and barnacles) can also affect the offshore infrastructure and its performance. Thus, one of the main challenges of the development of MRE is to understand how biofouling affects turbine performance.

## **8. Important Gaps within the OWF Environmental Impact Assessment (EIA) Studies**

The EIA considers the sensitivity to potential disruptions of some groups of valuable species without accounting for the links between them [27]. Thus, the effects of the construction of OWFs on the structure and function of the ecosystem remain unclear. There is an urgent need for the OWF EIA to adopt a holistic and integrated view of the ecosystem in their analyses. Additionally, iconic or flagship species are particularly emphasized for their endangered status and popularity among the masses [51]. Thus, monitoring of biological entities other than top predators, particularly within the benthic community (including hard artificial structures), has not yet been sufficiently accounted for [27, 51, 52]. However, several studies have stressed the need to include the benthos within ecosystem monitoring of the MREs [51, 52]. As mentioned below, the reef effect is considered to be the most important impact on the ecosystem with the arrival of new species. It is thus necessary to analyze the evolution of this new hard-substrate community. Additionally, a European review concluded that knowledge of changes in the functioning of soft-bottom benthic ecosystems due to MRE operations is limited and will require hypothesis-driven research combined with ecological modeling. This study also revealed that benthic sensitivity to MRE is higher than previously indicated [51]. Finally, Dannheim et al. (2019) [52] stressed the urgency to integrate benthic research on the MRE impact assessment with scientific approaches at the ecosystem level.

## **9. Next steps**

The hydrodynamic of the Alderney Race is very complex, and further research is necessary to understand the physical mechanisms and their impacts on sediment transport and macrofauna. The M2C researchers are planning to work on the characterization of the current shear and the interactions between waves, current, and turbulence near the bottom.

Laboratory experiments will be conducted to evaluate the impacts of species on the turbulent flow near the blade and in the wake. These results will be compared to the numerical results acquired by the M2C researchers.

The reef effect creates important hard-bottom macrobenthic biomasses, but it also increases the availability of prey to higher trophic levels, especially demersal fishes. It will be essential to identify the part of the benthic biomass consumed by fish around the EMR by using stomach content or isotope analyses to construct a more realistic trophic model due to EMR deployments. This approach was proposed by the M2C laboratory for the CSM EMR site simultaneously with the evaluation of the changes in the soft-bottom and hard-bottom communities. The role of the EMR structures as a source for connecting populations of various species with a benthopelagic development began in October 2020 in the framework of a three-year Ph. D. program. This topic involved benthologists and physicians ensuring a multi-disciplinary approach by the M2C laboratory to establish the English Channel as a model for the Megatidal Sea, where humans are highly dependent on the coastal ecosystem, which is under strong environmental forces.
